***Abstract*—Aerological data of the days, when upward lightning flashes with large charge transfer in winter were observed, were analyzed. Indices used for the evaluation of stability of air in the convective season, are not suitable to apply to winter lighting condition; however, a modified index derived from arerological data seems to be related to the days when upward flashes occur, including occurrence of energetic upward flashes.**

***Keywords*—lightning, winter lightning, aerological data, upward lightning, wind turbine**

I. INTRODUCTION

Lightning flashes hitting tall structures in winter in the coastal area of the Sea of Japan are mostly upward lightning [Ishii et al., 2009, 2011, 2013, 2014; Natsuno et al., 2010; NEDO report, 2015; Saito and Ishii, 2016, 2017a, 2017b]. Characteristics of such upward lightning in winter are different from those of downward lightning observed in the convective season, especially in the current parameters.

Lightning currents were directly observed at 27 wind turbines in Japan in the 5-year research project, from 2008 to 2013, of NEDO (New Energy and Industrial Technology Development Organization), Japan. The extensive observation provided statistical data on lightning currents flew into wind turbines by direct lightning hits, and the data facilitate improvement of lightning protection of wind turbines. The ratio of the flashes with transferred charge exceeding 300 C, which may threat wind turbines, was 4% [NEDO report, 2015; Saito and Ishii, 2016].

Classification of weather pattern related to severity of winter thunderstorms by using the weather chart was tried [NEDO report, 2015], however, automatic classification of weather charts is still difficult. In the convective season, likeliness of occurrence of thunderstorms is evaluated from aerological data by using such indices as Showalter index, Total Totals, SWEAT index, K index etc. [Vogel, S. et al., 2016a, 2016b, 2017a, 2017b; Fujisawa and Kawamura, 2005], though, these indices are reportedly not quite suitable for winter lightning condition [Fujisawa and Kawamura, 2005].

This paper reports on the indices calculated from aerological data on the days when upward lighting flashes hit wind turbines in winter, in addition on days when upward flashes with large charge transfer were observed.

II. DATA SUBJECT TO ANALYSIS

676 lightning currents were observed during 5 seasons from October to April at the NEDO research project [NEDO report, 2015; Saito and Ishii, 2016]. In other months, only 10 data were recorded as shown in Fig. 1(a), although observation was carried out through the year.

Almost all of recorded currents were associated with upward lightning, and in this paper, the 676 lightning currents are classified as winter lightning. 27 lightning flashes with transferred charge exceeding 300 C were observed in winter months from December to March only, as seen in Fig. 1(b). These monthly distributions of Fig. 1 (a) and (b) look somewhat different. This suggests that there may be difference in the charge structures of thunderclouds in winter between majority of thunderclouds and those produce energetic upward lightning. Fig. 2 shows differences in the polarity of flashes belonging to these two groups, ordinary and energetic ones. Bipolar flashes are the majority in the energetic flashes.

The aerological data were observed at upper air observatories in Japan every 12 hours (9h JST, 21h JST). So upward flashes observed in a half-day bin (12hours) are grouped to form one datum. As the majority of observed upward flashes were on Honshu Island, the data obtained on this island only are analyzed. Consequently, 327 half-day aerological data from November to March, on days upward flashes were observed, are analyzed.

Aerological data [http://weather.uwyo.edu/upperair/] obtained at three upper air observatories are used, and data from instrumented wind turbines are analyzed in conjunction with the data from the closest upper air observatory. Observed lightning flashes are put in the half-day bin with the closest observation time of upper air data. The locations of wind turbines and upper air observatories are shown in Fig. 3. Among the analyzed 327 half-days, 23 half-days had flashes with transferred charge exceeding 300 C.

III. Monthly Variation of Meteorologial Data

Fig. 4 shows averaged monthly variations of meteorological parameters at each atmospheric pressure level at Wajima Observatory. Fig. 5 shows the atmospheric stability for the 327 half days, evaluated by using various indices employing criteria for prediction of occurrence of thunderstorms in the convective season. The thresholds of each criterion are shown in Table 1 [http://weather.uky.edu/kind.html]. As shown in Fig. 5, the judgements are not successful in both populations of all flashes and of energetic flashes except by Total Totals. Total Totals shows better judgement, however, there is not clear distinction between the ordinary and energetic flashes.

Fig. 5 Evaluated stability by using various indices when upward winter lightning occurred at wind turbines, by employing criteria for prediction of occurrence of thunderstorms in the convective season.

Table 1 Thresholds of classifications used to produce Fig. 5 and Fig. 6.

K index	Unstable > 18 > Stable
Total Totals	Unstable > 43 > Stable
SWEAT index	Unstable > 272 > Stable
Showalter index	Unstable < 4 < Stable

The reason for the unfavorable results except by Total Totals may be difference between the convective and non-convective seasons in altitudes where charge separation actively occurs. –10°C isotherm level, which is the temperature height where charge in thunderclouds frequently accumulates regardless of the season [Ishii et al., 2011], considerably varies dependent on the season.

The height of –10°C is around 500 hPa in a typical summer month (August) and is around 850 hPa in a typical winter month (January) in Japan, whereas the indices used to evaluate atmospheric stability are mainly calculated by using aerological conditions between 850 and 500 hPa. Amount of water vapor in the atmosphere is important for formation of cloud particles, and is mostly from the surface of warm current in the Sea of Japan at winter lightning condition in Japan. This situation and meteorological parameters at each pressure level are quite different between summer and winter in Japan. Thus, criteria to judge stability useful in the convective season will need modification for winter condition.

Considering the different condition between summer and winter, Showalter index is calculated by using meteorological parameters at modified levels, 925 and 700 hPa, as shown in formula (1). The result of evaluated stability by using the modified Showalter index calculated by using (1) is shown in Fig. 6.

Level adjusted Showalter Index

$$= T\,(700\text{ hPa}) - T_p\,(\text{from } 925 \text{ hPa to } 700\text{ hPa}) \qquad (1)$$

Here, T is temperature, and Tp is temperature of lifted parcel.

By conventional Showalter index calculated from parameters at 850 and 500 hPa, most of the conditions are judged stable, because 1) T(500 hPa) is too cold to evaluate convective activity, 2) the moist adiabatic lapse rate and the dry adiabatic lapse rate are quite close at temperatures between 850 hPa and 500 hPa levels in winter. The modified index evaluated from parameters at adjusted levels, however, shows better performance to evaluate stability of winter lightning condition, and the calculated values of the index move to unstable sides. Fig. 6 shows the stability evaluated by the modified Showalter index by using the same threshold value, 4, shown in Table 1. Most half days are evaluated as unstable when upward flashes hit wind turbines.

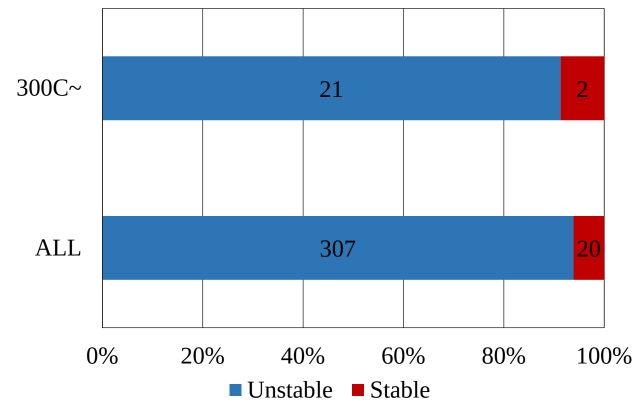

Fig. 6 Evaluated stability at winter thunderstorms by using modified Showalter index.

IV. Energetic Upward Flashes in Winter

As shown in Fig. 6, the most half days are evaluated as unstable by the modified Showalter index, however, there is not much difference in the index for half days with and without upward flashes associated with charge transfer over 300 C.

Fig. 7 show the relationship between the maximum transferred charge of a flash in a half day and the corresponding modified Showalter index of the half day. Most of the energetic flashes exceeding 400 C were observed on the half day, when the modified Showalter index is in between 1 and 4.

This result suggests that upward flashes with extremely large charge transfer tend to occur in the less convective condition among days with unstable air. This concentration of half days with energetic flashes on days of less active convection agrees to the tendency of the study using LLS data [Vogel. et al., 2017b] that energetic upward flashes more likely occur at thunderstorms of moderate activity.

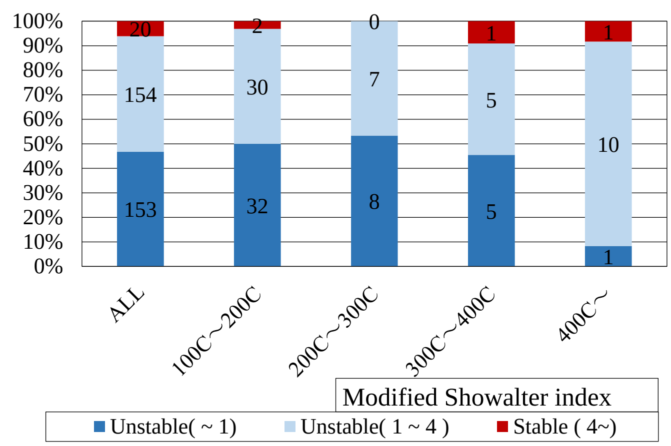

Fig. 7 Distribution of evaluated instability dependent on maximum transferred charge in a half day.

V. CONCLUSION

Aerological data when upward flashes were observed at instrumented wind turbines on the coast of the Sea of Japan in winter are analyzed. Criteria to calculate indices to evaluate atmospheric stability in the convective season are not suitable to evaluate condition of winter thunderstorms; however, by modifying the calculation condition, Showalter index turns out to be effective in evaluating stability in winter. Moreover, days of storms which produce energetic lightning flashes seem be separated by using this modified Showalter index. Such flashes associated with large charge transfer were observed more frequently when activity of convection was moderate.
